arXiv:1006.3894v1 [cs.NI] 19 Jun 2010

Abstract

Hahn and Wallsten [1] wrote that network neutrality "usually means that broadband service providers charge consumers only once for Internet access, do not favor one content provider over another, and do not charge content providers for sending information over broadband lines to end users." In this paper we study the implications of non-neutral behaviors under a simple model of linear demand-response to *usage-based* prices. We take into account advertising revenues and consider both cooperative and non-cooperative scenarios. In particular, we model the impact of side-payments between service and content providers. We also consider the effect of *service discrimination* by access providers, as well as an extension of our model to non-monopolistic content providers.

I. Introduction

Network neutrality is an approach to providing network access without unfair discrimination among applications, content or traffic sources. Discrimination occurs when there are two applications, services or content providers that require the same network resources, but one is offered better quality of service (shorter delays, higher transmission capacity, *etc.*) than the other. How to define what is "fair" discrimination is still subject to controversy.[5] A preferential

[5] The recent decision on Comcast v. the FCC was expected to deal with the subject of "fair" traffic discrimination, as the FCC ordered Comcast to stop interfering with subscribers' traffic generated by peer-to-peer networking applications. The Court of Appeals for the District of Columbia Circuit was asked to review this order by Comcast, arguing not only on the necessity of managing scarce network resources, but also on the non-existent jurisdiction of the FCC over network management practices. The Court decided that the FCC did not have express statutory authority over the subject, neither demonstrated that its action was "reasonably ancillary to the [...] effective performance of its statutorily mandated responsibilities". The FCC was deemed, then, unable to sanction discriminatory practices on Internet's traffic carried out by American ISPs, and the underlying case on the "fairness" of their discriminatory practices was not even discussed.

treatment of traffic is considered fair as long as the preference is left to the user.[6] Internet Service Providers (ISPs) may have interest in traffic discrimination either for technological or economic purposes. Traffic congestion, especially due to high-volume peer-to-peer traffic, has been a central argument for ISPs against the enforcement of net neutrality principles. However, it seems many ISPs have blocked or throttled such traffic independently of congestion considerations.

ISPs recently claimed that net neutrality acts as a disincentive for capacity expansion of their networks. In [2], the authors studied the validity of this argument and came to the conclusion that, under net neutrality, ISPs invest to reach a social optimal level, while they tend to under/over-invest when neutrality is dropped. In their setting, ISPs stand as winners while content providers (CPs) are left in a worse position, and users who pay the ISPs for preferential treatment are better off while other consumers have a significantly worse service.

ISPs often justify charging CPs by quantifying the large amount of network resources "big" content providers use. On the other hand, the content a CP offers contributes to the demand for Internet access, and thus benefits the access providers.

Many references advocate the use of the Shapley value as a fair way to share profits between the providers, see, *e.g.*, [4], [5]. One of the main benefits of this approach is that it yields Pareto optimality for all players, and requires in particular that CPs, many of whom receive third-party income such as advertising revenue from consumers' demand, help pay for the network access that makes this new income possible.

In this paper, we focus on violations of the neutrality principles defined in [1] where broadband service providers

- charge consumers more than "only once" through usage-based pricing, and
- charge content providers through side-payments.

Within a simple game-theoretic model, we examine how regulated[7] side payments, in either direction, and demand-dependent advertising revenues affect equilibrium usage-based prices. We also address equilibria in Stackelberg leader-follower dynamics.

The rest of the paper is organized as follows. In section II, we describe a basic model and derive Nash equilibria for competitive and collaborative scenarios. We consider potentially non-neutral side-payments in section III and add advertising revenues in section IV, analyzing in each case how they impact equilibrium utilities. We study an ISP offering multiple service classes in section V, and generalize our model in section VI to non-monopolistic content or access providers. In section VII, we consider leader-follower dynamics. We conclude in section VIII and discuss future work.

[6] Nonetheless, users are just one of many actors in the net neutrality debate, which has been enliven [?] throughout the world by several public consultations for new legislations on the subject. The first one, proposed in the USA, was looking for the best means of preserving a free and open Internet. The second one, carried out in France, asks for different points of view over net neutrality. A third one is intended to be presented by the EU during summer 2010, looking for a balance on the parties concerned as users are entitled to access the services they want, while ISPs and CPs should have the right incentives and opportunities to keep investing, competing and innovating. See [7], [3], [6].

[7] In the European Union, dominating positions in telecommunications markets (such as an ISP imposing side-payments to CPs at a price of his choice) are controlled by the article 14, paragraph 3 of the Directive 2009/140/EC, considering the application of remedies to prevent the leverage of a large market power over a secondary market closely related.

II. BASIC MODEL

Our model encompasses three actors:

- the internauts (users), collectively,
- a network access provider for the internauts, collectively called ISP1, and
- a content provider and its ISP, collectively called CP2.

The two providers play a game to settle on their (usage-based) prices. The internauts are modeled through their demand response.

Consumers are assumed willing to pay a usage-based fee (which can be \$0/byte) for service/content that requires both providers.

Denote by $p_i \geq 0$ the usage-based price leveed by provider i (ISP1 being $i = 1$ and CP2 being $i = 2$). We assume that the demand-response of customers, which corresponds to the amount (in bytes) of content/bandwidth they are ready to consume given prices p_1 and p_2, follows a simple linear model:

$$D = D_0 - d(p_1 + p_2). \tag{1}$$

With such a profile, we are dealing with a set of homogeneous users sharing the same response coefficient d to price variations. Parameter D_0 corresponds to demand for zero usage-based prices, which can be considered the demand under pure *flat-rate* pricing assuming that the usage-based prices are overages on flat montly fees.

Demand should be non-negative, *i.e.*,

$$p_1 + p_2 \;\leq\; \frac{D_0}{d} \;=:\; p_{\mathsf{max}}.$$

Provider i's usage-based revenue is given by

$$U_i \;=\; Dp_i. \tag{2}$$

A. Competition

Suppose the providers do not cooperate. A Nash Equilibrium Point (NEP) (p_1^*, p_2^*) of this two-player game satisfies:

$$\frac{\partial U_i}{\partial p_i}(p_1^*, p_2^*) = D^* - p_i^* d = 0 \quad \text{for } i = 1, 2,$$

which leads to $p_1^* = p_2^* = D_0/(3d)$. The demand at equilibrium is thus $D^* = D_0/3$ and the revenue of each provider is

$$U_i^* = \frac{D_0^2}{9d}. \tag{3}$$

B. Collaboration

Now suppose there is a coalition between ISP1 and CP2. Their overall utility is then $U_{\mathsf{total}} := U_1 + U_2 = Dp$, and an NEP (p_1^*, p_2^*) satisfies

$$\frac{\partial U_{\mathsf{total}}}{\partial p_i}(p_1^*, p_2^*) \;=\; D^* - d(p_1^* + p_2^*) \;=\; 0 \quad \text{for } i = 1, 2,$$

which yields $p^* := p_1^* + p_2^* = D_0/(2d)$. The demand at equilibrium is then $D^* = D_0/2$, greater than in the non-cooperative setting. The overall utility $U_{\mathsf{total}}^* = D_0^2/(4d)$ is also greater than $D_0^2/(4.5d)$ for the competitive case. Assuming both players share this revenue equally (trivially, the Shapley values are $\{1/2, 1/2\}$ in this case), the utility per player becomes

$$U_i^* = \frac{D_0^2}{8d}, \tag{4}$$

which is greater than in the competitive case. So, both players benefit from this coalition.

III. Side-Payments under Competition

Let us suppose now that there are *side payments* between ISP1 and CP2 at (usage-based) price p_s. The revenues of the providers become:

$$U_1 = D\left(p_1 + p_s\right) \tag{5}$$

$$U_2 = D\left(p_2 - p_s\right) \tag{6}$$

Note that p_s can be positive (ISP1 charges CP2 for "transit" costs) or negative (CP2 charges ISP1, *e.g.*, for copyright remuneration[8]). It is expected that p_s is *not* a decision variable of the players, since their utilities are monotonic in p_s and the player without control would likely set (usage-priced) demand to zero to avoid negative utility. That is, p_s would normally be *regulated* and we will consider it as a fixed parameter in the following (with $|p_s| \leq p_{\mathsf{max}}$).

First, if $|p_s| \leq \frac{1}{3}p_{\mathsf{max}}$, the equilibrium prices are given by

$$p_1^* = \frac{1}{3}p_{\mathsf{max}} - p_s$$
$$p_2^* = \frac{1}{3}p_{\mathsf{max}} + p_s$$

but demand $D^* = D_0/3$ and utilities

$$U_i^* = \frac{D_0^2}{9d}$$

are exactly the same as (3) in the competitive setting with no side payment. Therefore, though setting $p_s > 0$ at first seems to favor ISP1 over CP2, it turns out to have no effect on equilibrium revenues for both providers.

Alternatively, if $p_s \geq \frac{1}{3}p_{\mathsf{max}}$, a boundary Nash equilibrium is reached when $p_1^* = 0$ and $p_2^* = \frac{1}{2}(p_{\mathsf{max}} + p_s)$, which means ISP1 does not charge usage-based fees to its consumers. Demand becomes $D^* = \frac{1}{2}(D_0 - dp_s)$, and utilities are

$$U_1^* = \frac{(D_0 - dp_s)dp_s}{2d}$$
$$U_2^* = \frac{(D_0 - dp_s)^2}{4d}$$

Though $p_1^* = 0$, U_1^* is still strictly positive, with revenues for ISP1 coming from side-payments (and possibly from flat-rate monthly fees as well). Furthermore, $p_s \geq \frac{1}{3}p_{\mathsf{max}} \Leftrightarrow dp_s \geq \frac{1}{2}(D_0 - dp_s)$, which means $U_1^* \geq U_2^*$: in this

[8]In France, a new law has been proposed recently to allow download of unauthorized copyright content, and in return be charged *proportionally* to the volume of the download.

setting, ISP1's best move is to set his usage-based price to zero (to increase demand), while he is sure to achieve better revenue than CP2 through side-payments.

Finally, if $p_s < -\frac{1}{3}p_{\mathsf{max}}$, the situation is similar to the previous case (with $-p_s$ instead of p_s). So, here $p_2^* = 0$ and $p_1^* = \frac{1}{2}(p_{\mathsf{max}} - p_s)$, leading to $U_2^* \geq U_1^*$.

To remind, herein revenues U_i are assumed usage-based, which means there could also be flat-rate charges in play to generate revenue for either party. Studies of flat-rate compare to usage-based pricing schemes can be found in the literature, see, *e.g.*, [8].

IV. Advertising revenues

We suppose now that CP2 has an additional source of (usage-based) revenue from advertising that amounts to Dp_a. Here p_a is not a decision variable but a fixed parameter.[9]

A. Competition

The utilities for ISP1 and CP2 are now:

$$U_1 = [D_0 - d \cdot (p_1 + p_2)]\,(p_1 + p_s) \tag{7}$$

$$U_2 = [D_0 - d \cdot (p_1 + p_2)]\,(p_2 - p_s + p_a) \tag{8}$$

Here, the Nash equilibrium prices are:

$$\begin{aligned} p_1^* &= \frac{1}{3}p_{\mathsf{max}} - p_s + \frac{1}{3}p_a \\ p_2^* &= \frac{1}{3}p_{\mathsf{max}} + p_s - \frac{2}{3}p_a \end{aligned}$$

The cost to users is thus $p^* = \frac{2}{3}p_{\mathsf{max}} - \frac{1}{3}p_a$ while demand is $D^* = \frac{1}{3}(D_0 + dp_a)$. Nash equilibrium utilities are given by

$$U_i^* = \frac{(D_0 + dp_a)^2}{9d} \quad \text{for } i = 1, 2, \tag{9}$$

which generalizes equation (3) and shows how advertising revenue quadratically raises players' utilities.

B. Collaboration

The overall income for cooperating providers is

$$U_{\mathsf{total}} = (D_0 - dp)(p + p_a). \tag{10}$$

So, solving the associated NEP equation yields

$$p^* = \frac{p_{\mathsf{max}} - p_a}{2}. \tag{11}$$

[9] One may see p_a as the result of an independent game between CP2 and his advertising sources, the details of which are out of the scope of this paper.

The NEP demand is then $D^* = (D_0 + dp_a)/2$, and the total revenue at Nash equilibrium is $U^*_{\mathsf{total}} = (D_0 + dp_a)^2/(4d)$. Assuming this revenue is split equally between the two providers, we get for each provider the equilibrium utility

$$U_i^* = \frac{(D_0 + dp_a)^2}{8d}, \tag{12}$$

which generalizes equation (4). As before, providers and users are better off when they cooperate.

Thus, we see that $p_a > 0$ leads to lower prices, increased demand and more revenue for *both* providers (*i.e.*, including ISP1).

V. ISP Providing Multiple Service Classes

In this section, we suppose ISP1 is offering two types of network access service: a low-quality one l at price p_l, and a high-quality one h at price $p_h \geq p_l$. The role of multiple service classes in a neutral network has previously been explored, *e.g.*, in [9]. Here, we split the demand D into D_l and D_h: $D = D_l + D_h$ (we will describe later how we implement the dichotomy between D_l and D_h). For now, assume the overall demand still has a linear response profile, *i.e.*,

$$D = D_0 - d(\underbrace{p_l + p_h}_{\text{formerly } p_1} + p_2). \tag{13}$$

First, we make reasonable assumptions on D_l:

1) *Pricing incentives:* Define $\Delta p := p_h - p_l$. Δp is an incentive for consumers to chose between classes l and h: the higher Δp is, the more likely users are to select l. Thus, if we take $x := 1/\Delta p$ and $y := D_l/D$, we may see y as a function of x and model this pricing response with the following properties:

$$y'(x) \leq 0 \quad (D_l \text{ increases with } \Delta p) \tag{14}$$

$$y(0) = 1 \quad (D_l \uparrow D \text{ as } \Delta p \uparrow \infty) \tag{15}$$

$$y(\infty) = 0 \quad (D_l \downarrow 0 \text{ as } \Delta p \downarrow 0) \tag{16}$$

2) *Congestion incentives:* As D_l approaches D, we assume congestion occurs in the low-quality network, further deterring users to chose it. This motivates the additional assumption that

$$|y'(x)| \downarrow 0 \text{ as } x \downarrow 0, \tag{17}$$

that is, D_l *decelerates* as it gets closer to D.

Define

$$\delta := \frac{\Delta p}{\gamma p_{\mathsf{max}}}, \tag{18}$$

where $\gamma > 0$ is an additional users' price-sensitivity parameter. The following demand relation satisfies all conditions (14), (15), (16) and (17):

$$D_l := \left(1 - e^{-\delta}\right) D. \tag{19}$$

The providers' utilities are then:

$$U_1 = D_l p_l + D_h p_h = D\left(p_l + \Delta p e^{-\delta}\right) \quad (20)$$

$$U_2 = D p_2 \quad (21)$$

A. Collaboration

If both players cooperate, their overall utility is

$$U_{\mathsf{total}} = D\left(p_2 + p_l + \Delta p e^{-\delta}\right).$$

There is no NEP with strictly positive prices $p_i \geq 0$ for $i = 1, 2$. To specify the boundary NEP (where at least one usage-based price is zero), define

$$\phi(x) := (1-x)e^{-x}$$

and note that ϕ is a bijection of $[0, 1]$.

- If $p_2 = 0$, NEP conditions imply

$$\delta^* = \phi^{-1}(1/2)$$
$$p_l^* = \frac{1}{3}\left(\frac{1}{2} - \gamma\delta e^{-\delta}\right) p_{\mathsf{max}}$$

  Utility at the NEP is therefore

$$U^*_{\mathsf{total}} = \frac{D_0^2}{9d}\left[\frac{1}{2} + 2\gamma\delta e^{-\delta}\right].\left[2 + \left(2e^{-\delta} - 3\right)\delta\gamma\right] \quad (22)$$

  In this setting, the value of U_{total} is upper bounded by $\approx\ 0.162\frac{D_0^2}{d}$ which is achieved when $\gamma \approx 1.53$ (recall that γ is not a decision variable).

- If $p_l = 0$, then $p_h = 0$ and $p_2 = \frac{1}{2}p_{\mathsf{max}}$, yielding

$$U_{\mathsf{total}} = \frac{D_0^2}{4d}. \quad (23)$$

Hence, irrespective of consumers' sensitivity γ to the price gap Δp, the best solution for the coalition is to set-up usage-based pricing for content only, at price $p_2 = p_{\mathsf{max}}/2$, while network access is subject only to flat-rate pricing ($p_l = p_h = 0$).

B. Splitting Demand-Response Coefficient

Now consider splitting the demand-response coefficient d into d_l, d_h and d_2, that is:

$$D = D_0 - d_l p_l - d_h p_h - d_2 p_2. \quad (24)$$

If

$$d_2 = d_l + d_h, \quad (25)$$

then the interior equilibrium conditions $\nabla U_{\mathsf{total}} = \vec{0}$ yield:

$$\begin{aligned} \delta &= \phi^{-1}(d_h/d_2) \\ p_l + p_2 &= \frac{D_0}{2d_2} - \frac{\delta \Delta p_0}{2}\left(\frac{d_h}{d_2} + e^{-\delta}\right) \end{aligned}$$

When the demand-response coefficients satisfy (25), we have an *equilibrium line*. Vector field plots of U_{total} suggest it is attractive (see Figure 1). In this particular setting, providers can thus reach U^*_{total} with usage-based pricing.

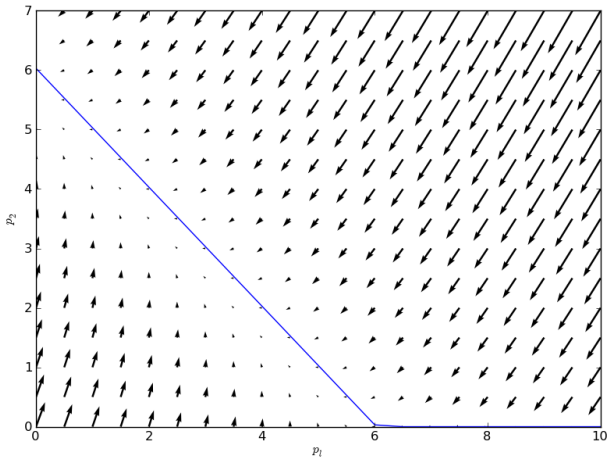

Fig. 1. Attraction of the equilibrium line.

However, if $d_2 \neq d_l + d_h$, there exists a line of attraction, but with a non-null gradient on it driving players toward border equilibria. Hence, the conclusion of subsection V-A also holds in this more generalized setting.

C. Competition

When ISP1 and CP2 compete, again there is no interior NEP (with all prices p_i strictly positive). In fact, the condition $\nabla_{p_l,p_h} U_1 = \vec{0}$ implies $p_l = 0 = p_h$ and $D = 0$, so ISP1 has to relax condition $\frac{\partial U_1}{\partial p_l} = 0$ by setting $p_l = 0$ (*i.e.*, only flat-rate pricing for the best-effort service l). The solution to the two remaining Nash equilibrium conditions is then:

$$p_2 = \frac{1}{4}\left[\sqrt{9\gamma^2 + 2\gamma + 1} - 3\gamma + 1\right] \cdot p_{\mathsf{max}} \tag{26}$$

$$p_h = \frac{\gamma}{2\sqrt{9\gamma^2 + 2\gamma + 1} - 3\gamma + 2} \cdot p_{\mathsf{max}} \tag{27}$$

By defining $f_2(\gamma) := p_2/p_{\mathsf{max}}$ and $f_h(\gamma) := p_h/p_{\mathsf{max}}$, we then have

$$\begin{aligned} U_1^*(\gamma) &= f_h(\gamma) \cdot (1 - f_h(\gamma) - f_2(\gamma)) D_0 p_{\mathsf{max}} \\ U_2^*(\gamma) &= f_2(\gamma) \cdot (1 - f_h(\gamma) - f_2(\gamma)) D_0 p_{\mathsf{max}} \end{aligned}$$

Figure 2 shows utilities at equilibrium (as fractions of $D_0 p_{\mathsf{max}}$). We see that, in any case, CP2 has the advantage in this game: U_2^* is always greater to U_1^*, irrespective of consumers' sensitivity γ to usage-based prices.

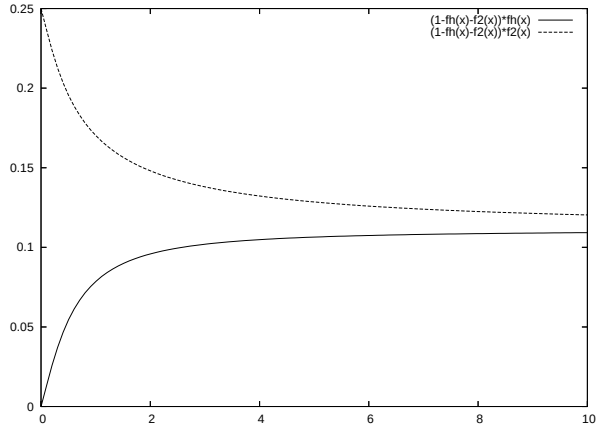

Fig. 2. Utilities as functions of users' sensitivity to usage-based pricing.

Here, $\gamma \to 0$ means users are so sensitive to any usage-based price that they will always choose the best-effort service (which is subject to flat-rate pricing). Users' price sensitivity decreases as γ increases, the limit $\gamma \to \infty$ corresponding to the setting of section II with $\lim_{\gamma\to\infty} U_i^*(\gamma) = \frac{D_0^2}{9d}$.

VI. Multiple CPs providing the same type of content

Now suppose there are multiple CPs supplying the *same* type of content (*e.g.*, competing online encyclopedias), so users choose one CP over another based only on price.

For the sake of simplicity, let us consider the case with two CPs denoted by CP2 and CP3. First, let us remark that if there is a significant difference between the prices p_2 of CP2 and p_3 of CP3, since both provide the same type of content, all consumers are likely to shift to the cheapest provider, leading us back to our initial model with one ISP and one CP.

So the difference introduced by multiple CPs may arise when $p_2 \approx p_3$. Suppose that, initially,

$$p_2 = \bar{p} = p_3.$$

In this case, we assume customers are evenly shared between CP2 and CP3, so that

$$U_i = \frac{1}{2} D(p_1, \bar{p})\bar{p} \quad \text{for } i = 2, 3,$$

where $D(p_1, p_i) := D_0 - d(p_1 + p_i)$ is the demand-reponse to the usage-based prices p_1 (for network access) and p_i (for content).

Now, if CPi reduces its price by some small δp_i, some of its opponent's consumers will change CP, but not all of them since a small price gap may not convince them to go. This behavior is known as *customer stickiness, inertia or loyalty*. To model it we rewrite U_i as

$$U_i \;=\; s(p_i, p_{5-i}) D(p_1, p_i) p_i \quad \text{for } i = 2, 3, \tag{28}$$

where p_{5-i} denotes the usage-based price of the other CP, and the "stickiness" function s has the following properties:

$$s(x,y) \geq 0, \tag{29}$$

$$s(x,x) = \frac{1}{2}, \tag{30}$$

$$s(x,y) + s(y,x) = 1. \tag{31}$$

When CPi reduces its price by δp_i, the first-order variation in its utility is given by $\frac{\partial U_i}{\partial p_i}(\bar{p},\bar{p})\delta p_i$. From (28) and (31),

$$\frac{\partial U_i}{\partial p_i}(\bar{p},\bar{p}) = \left[\frac{\partial s}{\partial x}(\bar{p},\bar{p}) + \frac{p_{\mathsf{max}} - p_1 - 2\bar{p}}{2\bar{p}(p_{\mathsf{max}} - p_1 - \bar{p})}\right] D(p_1,\bar{p})\bar{p}.$$

(Where p_{max} was defined as $\frac{D_0}{d}$.) Thus, taking consumers loyalty into consideration, the Nash equilibrium condition for either CPi becomes:

$$\frac{\partial s}{\partial x}(\bar{p},\bar{p}) + \frac{p_{\mathsf{max}} - p_1 - 2\bar{p}}{2\bar{p}(p_{\mathsf{max}} - p_1 - \bar{p})} = 0. \tag{32}$$

A. Stickiness Model 1

As a first, simple loyalty model, suppose that after CPi reduces its price by δp_i, the fraction of users that remain with the other CP$(5-i)$ is inversely proportional to its price p_{5-i}, *i.e.*, the stickiness function is

$$s(p_i,p_{5-i}) := \frac{1/p_i}{1/p_i + 1/p_{5-i}} = \frac{p_{5-i}}{p_i + p_{5-i}}. \tag{33}$$

In this setting, equilibrium condition (32) becomes $\bar{p} = \frac{1}{3}(p_{\mathsf{max}} - p_1)$, while equilibrium condition for ISP1 is $p_1 = \frac{1}{2}(p_{\mathsf{max}} - \bar{p})$. Thus, prices at the NEP are $p_1^* = \frac{2}{5}p_{\mathsf{max}}$ and $\bar{p}^* = \frac{1}{5}p_{\mathsf{max}}$. Demand at equilibrium is $D^* = \frac{2D_0}{5d}$ and the revenue of each provider is

$$U_1^* = \frac{4}{25}U_{\mathsf{max}}, \tag{34}$$

$$U_i^* = \frac{1}{25}U_{\mathsf{max}} \quad \text{for } i = 2,3. \tag{35}$$

We see that, compared to (3), ISP1 highly benefits from the competition between CPs (his revenue is about 44% higher). The situation would be symmetric with a single CP and two competing ISPs.

B. Stickiness Model 2

One can consider another loyalty model where the fraction of users remaining with CP$-i$ is proportional to the price *slackness* $p_{\mathsf{max}} - p_{5-i}$, *i.e.*, the stickiness function is

$$s(p_i,p_{5-i}) := \frac{p_{\mathsf{max}} - p_i}{(p_{\mathsf{max}} - p_i) + (p_{\mathsf{max}} - p_{5-i})}$$

Here condition (32) becomes $2(p_{\mathsf{max}} - \bar{p})(p_{\mathsf{max}} - p_1 - 2\bar{p}) = \bar{p}(p_{\mathsf{max}} - p_1 - \bar{p})$, while equilibrium condition for ISP1 is still $2p_1 + \bar{p} = p_{\mathsf{max}}$. Resolution of this system leads to $p_1^* = \frac{5}{14}p_{\mathsf{max}}$ and $\bar{p}^* = \frac{2}{7}p_{\mathsf{max}}$. At the NEP, demand

is thus $D^* = \frac{5}{14} D_0$ and utilities are

$$\begin{aligned} U_1^* &= \frac{25}{196} U_{\mathsf{max}} \approx 0.12\, U_{\mathsf{max}}, \\ U_i^* &= \frac{10}{196} U_{\mathsf{max}} \approx 0.051\, U_{\mathsf{max}} \quad \text{for } i = 2, 3. \end{aligned}$$

We see with this second setting that the outcome of the price war between CPs and ISP1 significantly depends on the customer inertia model used.

C. Stickiness with side-payments

Now focusing on the first stickiness model (33) and update the model to take into account usage-based side payments p_s. The revenues become

$$\begin{aligned} U_1 &= D(p_1 + p_s), \\ U_i &= s(p_i, p_{5-i}) D(p_i - p_s) \quad \text{for } i = 2, 3. \end{aligned}$$

For same-priced CPs, solving $\frac{\partial U_i}{\partial p_i}(\bar{p}, \bar{p}) = 0$ (with non-nul demand), we find that the equilibrium conditions are

$$\begin{aligned} (\bar{p} - p_s)(p_{\mathsf{max}} - p_1 + \bar{p}) &= 2\bar{p}(p_{\mathsf{max}} - p_1 - \bar{p}), \\ 2p_1 &= p_{\mathsf{max}} - \bar{p} - p_s. \end{aligned}$$

They are now quadratic in $\bar{p}$, thus, for the sake of readability, let us define

$$\begin{aligned} \eta &:= p_s / p_{\mathsf{max}}, \text{ and} \\ \psi(\eta) &:= \sqrt{1 + 28\eta + 36\eta^2}. \end{aligned}$$

When $p_s > 0$ (side payments from the CPs to the ISP), resolution of this system for positive prices lead us to:

$$\begin{aligned} \bar{p}^* &= \frac{p_{\mathsf{max}}}{10} (1 + 4\eta + \psi(\eta)) \\ p_1^* &= \frac{p_{\mathsf{max}}}{20} (9 - 14\eta - \psi(\eta)) \end{aligned}$$

Then, demand at the NEP is $D^* = \frac{D_0}{20}(9 + 6\eta - \psi(\eta))$ while revenues are

$$U_1^* = \frac{U_{\mathsf{max}}}{400}(9 + 6\eta - \psi(\eta))^2 \tag{36}$$

$$U_i^* = \frac{U_{\mathsf{max}}}{100}(2 - 19\eta - 18\eta^2 + (2 + 3\eta)\psi(\eta)) \tag{37}$$

What is interesting here is that both utilities are monotone in η (see Figure 3): U_1^* decreases while U_i^* increases with η (when $p_s \ll p_{\mathsf{max}}$, we fall back to the results (34) and (35) of subsection VI-A). Paradoxically enough, we see that increasing p_s (which means more usage-based side payments for ISP1) is disadvantageous for ISP1 but benefits the CPs! This situation is very different from the one in section III, where the ISP was favored over the CP when η was over a fixed threshold.

When $p_s < 0$, CPs receive usage-based side payments from ISP1 (ostensibly for royalties of copyrighted content).

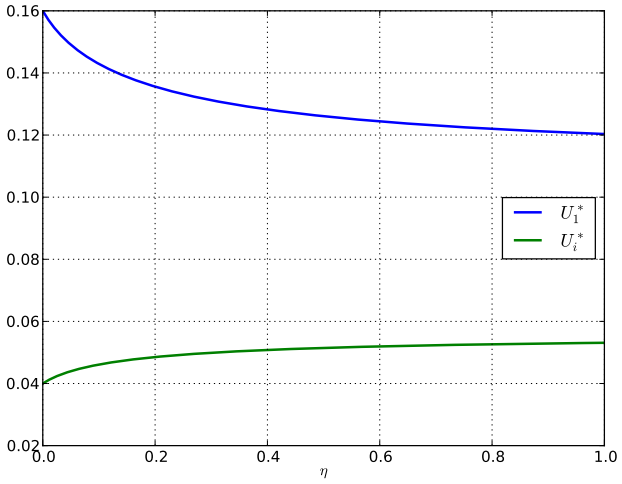

Fig. 3. Revenues at the NEP as functions of $\eta := p_s/p_{\mathsf{max}}$.

If $p_s \leq \frac{-7+2\sqrt{10}}{18} p_{\mathsf{max}}$, then $\frac{\partial U_i}{\partial p_i}(\bar{p}, \bar{p})$ is always negative and $\bar{p}$ will tend to zero. This means that the best strategy for CPs is to offer their content only for a flat rate, thus increasing demand and making all their usage-based profits on side payments.

Otherwise, if $p_s > \frac{-7+2\sqrt{10}}{18} p_{\mathsf{max}}$, then condition (32) has two solutions:

$$\begin{aligned} \bar{p}_0 &= \frac{1}{10}(4\eta + 1 - \psi(\eta)) p_{\mathsf{max}}, \\ \bar{p}_1 &= \frac{1}{10}(4\eta + 1 + \psi(\eta)) p_{\mathsf{max}}. \end{aligned}$$

There are therefore two equilibria:

- $\bar{p}^* = \bar{p}_1$ and $p_1^* = \frac{1}{20}(-14\eta + 9 - \psi(\eta))$: this is the case we studied in the $p_s > 0$ setting, demand and revenues at the NEP are unchanged. This equilibrium is "stable" in the sense that[10] $\frac{\partial U_i}{\partial p_i}(\bar{p}_1-, \bar{p}_1-) > 0$ and $\frac{\partial U_i}{\partial p_i}(\bar{p}_1+, \bar{p}_1+) < 0$ for $i \in \{2, 3\}$: if CPs move slightly their prices around $\bar{p}^* = \bar{p}_1$, they are incented to move back.
- $\bar{p}^* = \bar{p}_0$ and $p_1^* = \frac{1}{20}(-14\eta + 9 + \psi(\eta))$: in this case, demand at equilibrium is $D^* = \frac{D_0}{20}(9 + 6\eta + \psi(\eta))$ and revenues are given by

$$U_1^* = \frac{U_{\mathsf{max}}}{400}(9 + 6\eta + \psi(\eta))^2, \tag{38}$$

$$U_i^* = \frac{U_{\mathsf{max}}}{100}(2 - 19\eta - 18\eta^2 - (2 + 3\eta)\psi(\eta)). \tag{39}$$

  However, this equilibrium is "unstable" in the sense that $\frac{\partial U_i}{\partial p_i}(\bar{p}_1-, \bar{p}_1-) < 0$ and $\frac{\partial U_i}{\partial p_i}(\bar{p}_1+, \bar{p}_1+) > 0$: if CPs shift their prices from $\bar{p}^* = \bar{p}_0$, they are incented to shift even more, which will lead them either to the other equilibrium or to $\bar{p} = 0$ (again, no usage-based pricing for content, but there may additional revenue from flat-rate fees as well).

[10]Recall that we restrict our attention to $p_2 \approx p_3$.

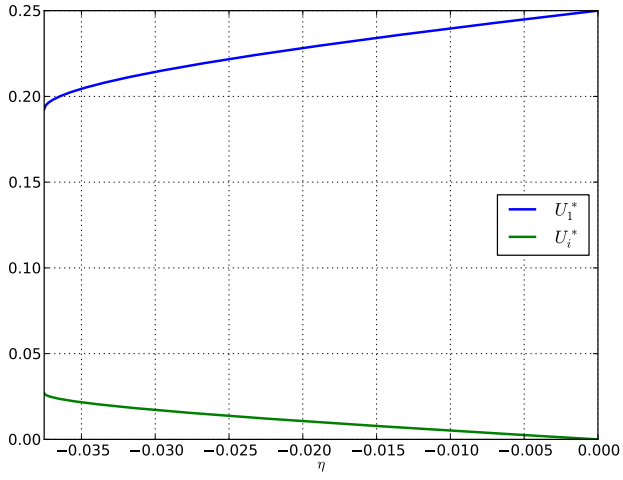

Fig. 4. Revenues at the unstable NEP as functions of η.

The ISP is better off at this new NEP (see Figure 4): regarless of the (regulated) value of p_s, his revenue is always higher here (and the CPs' revenues are always lower) than at the other NEP. This fact is consistent with the "unstability" we observed: if the CPs happen to leave this equilibrium, they are not incented to come back.

A similar story follows if one considers multiple competing ISPs with one CP. Also, taking advertising revenues into consideration will complicate the above computations and affect the location and "stability" of the NEPs.

VII. Stackelberg equilibrium

Stackelberg equilibrium corresponds to asymmetric competition in which one competitor is the leader and the other a follower. Actions are no longer taken independently: the leader takes action first, and then the follower reacts.

Though the dynamics of the games are different from the previous study, equations (7) and (8) still hold, with fixed $p_a \geq 0$ and regulated p_s. In the following, we need to assume that

$$\begin{aligned} p_s &\leq \frac{1}{2}p_{\mathsf{max}} + \frac{1}{2}p_a \\ p_a &\leq \frac{1}{3}p_{\mathsf{max}} + \frac{1}{4}p_s \end{aligned}$$

so that NEPs are reachable with positive prices.

If ISP1 sets p_1, then CP2's optimal move is to set

$$p_2 = \frac{1}{2}(-p_1 + p_{\mathsf{max}} + p_s - p_a).$$

This expression yields $D = \frac{d}{2}(p_{\mathsf{max}} - p_1 - p_s + p_a)$ and $U_1 = \frac{d}{2}(p_{\mathsf{max}} - p_1 - p_s + p_a)(p_1 + p_s)$. Anticipating CP2's reaction in trying to optimize U_1, the best move for ISP1 is thus to set

$$p_1^* = \frac{1}{2}p_{\mathsf{max}} - p_s + \frac{1}{2}p_a,$$

which yields

$$p_2^* = \frac{1}{4}p_{\mathsf{max}} + p_s - \frac{3}{4}p_a.$$

Therefore, when ISP1 is the leader, at the NEP demand is $D^* = \frac{1}{4}(D_0 + dp_a)$ and utilities are:

$$U_1^* = \frac{1}{8d}(D_0 + dp_a)^2, \tag{40}$$

$$U_2^* = \frac{1}{16d}(D_0 + dp_a)^2. \tag{41}$$

Suppose now that CP2 is the leader and sets p_2 first. Similarly, we find:

$$p_2^* = \frac{1}{2}p_{\mathsf{max}} + p_s - \frac{1}{2}p_a$$

$$p_1^* = \frac{1}{4}p_{\mathsf{max}} - p_s + \frac{1}{4}p_a$$

These values yield the same cost p^* and demand D^* for the internauts at the NEP, while providers' utilities become:

$$U_1^* = \frac{1}{16d}(D_0 + dp_a)^2, \tag{42}$$

$$U_2^* = \frac{1}{8d}(D_0 + dp_a)^2. \tag{43}$$

Therefore, in either case of leader-follower dynamics, the leader obtains twice the utility of the follower at the NEP (yet, his revenue is not better than in the collaborative case).

VIII. Conclusions and on-going work

Using a simple model of linearly diminishing consumer demand as a function of usage-based price, we studied a game between a monopolistic ISP and a CP under a variety of scenarios including consideration of: non-neutral two-sided transit pricing (either CP2 participating in network costs or ISP1 paying for copyright remuneration), advertising revenue, competition, cooperation and leadership.

In a basic model without side-payments and advertising revenues, both providers achieve the same utility at equilibrium, and all actors are better off when they cooperate (higher demand and providers' utility).

When regulated, usage-based side-payments p_s come into play, the outcome depends on the value of $|p_s|$ compared to the maximum usage-based price p_{max} consumers can tolerate:

- when $|p_s| \leq \frac{1}{3}p_{\mathsf{max}}$, providers shift their prices to fall back to the demand of the competitive setting with no side-payments;
- when $|p_s| \geq \frac{1}{3}p_{\mathsf{max}}$, the provider receiving side payments sets its usage-based price to zero to increase demand, while it is sure to be better off than his opponent.

When advertising revenues to the CP come into play, they increase the utilities of *both* providers by reducing the overall usage-based price applied to the users. ISP1 and CP2 still share the same utility at equilibrium, and the increase in revenue due to advertising is quadratic.

We considered in section V the implications of *service differentiation* from the ISP. In our model, when ISP1 and CP2 cooperate, the best solution for them is to set-up usage-based prices for content only and flat-rate pricing

for network access. However, when providers do not cooperate, the ISP optimally offers its best-effort service for a flat rate (zero usage-based cost), resulting in more usage-based revenue for the CP.

We considered in section VI a generalization of our model to non-monopolistic, competing CPs. For a simple customer inertia model, we found that regulated side-payments had a significant impact on equilibrium revenues for the ISP and the CPs:

- when side payments go to the access provider, his utility at the NEP diminishes, while
- when they go to the content providers, the three-player system has two equilibria: an unstable one in favor of the ISP, and a stable one.

Under leader-follower dynamics, the leader obtains twice the utility of his follower at equilibrium; yet, he does not achieve a better revenue than in the cooperative scenario.

In on-going work, we are exploring the effects of content-specific (*i.e.*, not *application* neutral) pricing, including multiple CPs providing different types of content.
